ABSTRACT
The volume expanding magnetostructural transition in \( \text{Mn}_3\text{GaC} \) and \( \text{Mn}_3\text{SnC} \) has been identified to be due to distortion of \( \text{Mn}_6\text{C} \) octahedra. Despite a similar lattice volume as \( \text{Mn}_3\text{SnC} \) and similar valence electron contribution to density of states as in \( \text{Mn}_3\text{GaC} \), \( \text{Mn}_3\text{InC} \) does not undergo a first order magnetostructural transformation like the Ga and Sn antiperovskite counterparts. A systematic investigation of its structure and magnetic properties using probes like x-ray diffraction, magnetization measurements, neutron diffraction, and extended x-ray absorption fine structure reveals that though the octahedra are distorted resulting in long and short Mn–Mn bonds and different magnetic moments on Mn atoms, the interaction between them remains ferromagnetic. This has been attributed to the strain on the \( \text{Mn}_6\text{C} \) octahedra produced due to a relatively larger size of In atoms compared to Sn and Ga. The size of In atoms constricts the deformation of \( \text{Mn}_6\text{C} \) octahedra giving rise to Mn–Mn distances that favor only ferromagnetic interactions in the compound.

I. INTRODUCTION
In ternary manganese carbides and nitrides ordering with a cubic antiperovskite (\( \text{Mn}_3\text{AB} \)) crystal structure, the magnetic ground state and physical properties can be significantly influenced by merely replacing the A-site atom.\(^2,3\) The A-site atoms like Ga, Cu, Zn, In, or Sn form a cubic cage enclosing a Mn\(_6\)C octahedra at its center. Numerous reports have illustrated a fascinating array of exotic properties displayed by such Mn antiperovskites just by replacing the A-site atom. For example, a tunable negative or zero thermal expansion (NTE) accompanying the volume discontinuous magnetic transition found in most of the nitrides (\( \text{Mn}_3\text{AN} \), A = Ga, Zn, etc.) is exceptionally absent in \( \text{Mn}_3\text{CuN} \).\(^4,5\) A substitution of Cu by Ge atoms favorably alters the number of valence electrons to induce the NTE property in \( \text{Mn}_3\text{Cu}_0\text{Ge}_{0.5}\text{N} \) around room temperature.\(^6\) Even in carbides, the first order magnetic transition seen at about 170 K in \( \text{Mn}_3\text{GaC} \)\(^7-9\) disappears completely with the replacement of Ga by Zn or Ge.\(^8\) The nature of the magnetocaloric effect is also different in \( \text{Mn}_3\text{GaC} \) and \( \text{Mn}_3\text{SnC} \). While \( \text{Mn}_3\text{GaC} \) displays an inverse magnetocaloric effect\(^9,10\), a normal magnetocaloric effect is seen in \( \text{Mn}_3\text{SnC} \).\(^11,12\) Recent extended x-ray absorption fine structure (EXAFS) studies on antiperovskites, \( \text{Mn}_3\text{GaC} \) and \( \text{Mn}_3\text{SnC} \), suggest that the magnetic and magnetocaloric properties mainly originate from local distortions restricted to the Mn sublattice.\(^12,13\) Even these distortions of the \( \text{Mn}_6\text{C} \) octahedra appear to be dependent on the type of the A-site atom. In \( \text{Mn}_3\text{GaC} \), the eightfold degenerate Mn–Mn bond splits into long (~3.1 Å) and short (~2.74 Å) distances at \( T_C = 242 \) K. The distortions are such that the Mn atoms are displaced from their face centered positions on a circular arc of radius equal to Mn–C bond length. An abrupt decrease in the shorter Mn–Mn distance at \( T \approx 175 \) K results in an AFM ground state and gives rise to a large positive...
magnetic entropy change ($\Delta S_m \sim 15 J/kg \cdot K$ at 2 T, equivalent to an adiabatic temperature difference of 3 K).\textsuperscript{9,13} Introduction of Sn for Ga at the A-site results in a lattice expansion as well as a change in the nature of the magnetocaloric effect from inverse to the conventional type with $\Delta S_m$ is about $-31 J/kg \cdot K$ at 2 T applied field.\textsuperscript{11} The larger size of Sn also seems to affect the distortions so as to cause the Mn$_8$C octahedra to elongate along one direction and shrink along the other two. As a result, the magnetic propagation vector, $k$, is $\frac{1}{2}$, $\frac{1}{2}$, $0$ in Mn$_8$SnC as against $\frac{1}{4}$, $\frac{1}{4}$, $\frac{1}{2}$ in Mn$_8$GaC.\textsuperscript{12}

The differences in the distortions of Mn$_8$C octahedra are preserved even in the solid solutions of Mn$_1$Ga$_{1-x}$Sn$_x$C and result in lattice strain\textsuperscript{15} as well as a cluster glassy ground state.\textsuperscript{9} Such a nonergodic ground state in Mn$_1$Ga$_{0.55}$Sn$_{0.45}$C was explained to be due to the formation of Ga rich and Sn rich clusters in the compound. Formation of such clusters could be due to some unique property of the A-site atom. Ga and Sn have two distinct differences, firstly their size and secondly their contribution of the valence electron density of states. In order to understand the exact cause of such distortions, we chose to investigate the structural and magnetic properties of Mn$_3$InC. It has a similar lattice volume as Mn$_8$SnC, while In contributes the same number of valence electrons as Ga. Furthermore, band structure calculations\textsuperscript{10} indicated that Mn$_3$InC should have similar properties as Mn$_3$GaC.\textsuperscript{17,18} Experimental reports on Mn$_3$InC are conflicting nature. Early reports indicate Mn$_3$InC to undergo a first order transition to a complex magnetic state that is similar to that of its Sn counterpart below $T_C \sim 272 K$\textsuperscript{19,20} while recent studies report a ferromagnetic ground state with a $T_C \sim 350 K$ followed by a transition to an antiferromagnetic state at about 140 K.\textsuperscript{21}

Therefore, in order to understand the exact nature of ground state in Mn$_3$InC, we report the results of a systematic investigation on the structural and magnetic properties of Mn$_3$InC. Furthermore, we use it as a prototypical compound to investigate the exact role of the A-site atom in the magnetostuctural transformation seen in the Mn based antiperovskites. We show that the distortions of Mn$_3$C octahedra are dependent on the size of the A-site atom. Comparatively, when the A-site is occupied by a smaller atom like Ga, the Mn$_3$C octahedra distort maximum resulting in a wider separation between long and short Mn–Mn bonds and an antiferromagnetic ground state. Larger A-site atoms like In, however, constrain the distortions of Mn$_3$C octahedra such as to prevent the formation of shorter Mn–Mn bonds that favor antiferromagnetic alignment and thus resulting in a ferromagnetic ground state.

II. EXPERIMENTAL

To synthesize polycrystalline Mn$_3$InC using the solid state reaction method, stoichiometric weights of powdered Mn and graphite were first thoroughly mixed with elemental In before the addition of 15% excess graphite powder. The resulting mixture was then pressed into a pellet, encapsulated in an evacuated quartz tube, and heated to 1073 K for the first 48 h before being annealed at 1150 K for the next 120 h.\textsuperscript{22} On cooling to room temperature, the crystallographic symmetry and phase purity of the compound formed were identified with the help of an x-ray diffraction (XRD) pattern recorded using Mo K$_\alpha$ radiation. Next, the magnetic properties of the prepared antiperovskite were determined by various field (0.01T and between $\pm 7 T$) and temperature dependent (5 K to 500 K) measurements carried out in a Vibrating Sample Magnetometer (Quantum Design). Furthermore, temperature dependent variations in the crystallographic and magnetic structures were traced by the Rietveld analysis\textsuperscript{23} of neutron powder diffraction patterns recorded on the PD-2 diffractometer ($\lambda = 1.2443 \AA$) at Dhruva reactor, Bhabha Atomic Research Center, Mumbai, India and E6 powder diffractometer ($\lambda = 2.4 A$) at the BERII reactor at Helmholtz Zentrum Berlin, Germany. In an attempt to comprehend the observed magnetic behavior of this material, a detailed examination of the local structure surrounding the Mn$_3$C octahedra is carried out by analyzing room temperature EXAFS spectra recorded in the transmission mode at 9C and NW10A at Photon Factory Synchrotron Source, Tsuchuba, Japan. During each measurement, both incident and transmitted intensities were simultaneously measured at the Mn/In K edges within the $-200$ to $1300 \text{eV}$ range using an ionization chamber filled with appropriate gases. Furthermore, the EXAFS [$\chi(k)$] signal is extracted by reducing the K edge data using well established procedures in the Demeter program.\textsuperscript{24}

III. RESULTS AND DISCUSSION

Rietveld analysis of the room temperature x-ray diffraction pattern recorded using Mo K$_\alpha$ ($\lambda = 0.7007 \text{A}$) radiation and presented in Fig. 1 indicates that the compound Mn$_3$InC forms within the cubic antiperovskite structure (Space Group: Pm\overline{3}m) along with impurities of In, In$_2$O$_3$, and MnO. The Mn to In ratio was found to be 3:1 from the refinement of the site occupancy of Mn and In in the antiperovskite phase. This ratio along with In contents was again independently verified from refinement of the neutron diffraction pattern described later in the paper. The structural and refinement parameters obtained for x-ray diffraction pattern are provided in Table I.

![Graph showing intensity vs. angular range](image-url)
Temperature dependent magnetization curves $[M(T)]$ presented for the compound in Fig. 2(a), over the 5–500 K temperature range, in an applied field of 0.01 T, under both zero field cooled (ZFC) and field cooled cooling (FCC) and field cooled warming (FCW) protocols exhibits a temperature dependence that differs from both Mn$_3$GaC and Mn$_3$SnC. The $M(T)$ curves suggest that the compound exhibits a broad transition from a PM to a FM state at $T_C \approx 377$ K followed by a sharp decrease in magnetization at $T = 127$ K resembling a transition to the AFM state. Finite magnetic moment even under zero field cooled state has forced classification of this state to be consisting of both FM and AFM components.$^{21}$ The FM character is also evident from the evolution of magnetization isotherms $[M(H)]$ measured for the sample at several temperatures both above and below 377 K as well as 127 K. The $M(H)$ curves recorded in magnetic fields up to ±7 T in Fig. 2(b) exhibit a similar behavior resembling ferromagnetic order at all temperatures in the interval 5 K $\leq T \leq 350$ K. An expanded view of the $M(H)$ virgin curves at low fields shown in the inset of Fig. 2(b) indicates a weakening of ferromagnetic interactions below 100 K. Furthermore, the presence of short range ferromagnetic interactions is also noted well above $T_C$ as indicated by the nonlinear $M(H)$ curve at 450 K.

In order to shed light on the exact nature of magnetic orderings in Mn$_3$InC, neutron diffraction patterns independently recorded with wavelengths $\lambda = 1.2443$ Å and $\lambda = 2.4$ Å were analyzed as a function of temperature. Rietveld refined structural parameters obtained from refining diffraction pattern recorded at 300 K using neutrons of 1.2443 Å are given in Table II. The ratio of Mn:C obtained from neutron diffraction was found to be 3:1. Indium content was estimated slightly lower than that obtained from x-ray diffraction, but this could be due to a larger absorption coefficient of In for thermal neutrons. It may also be seen that impurity phases of In and In$_2$O$_3$ are not detected from neutron diffraction.

Unlike its Ga and Sn counterparts that exhibit pure magnetic reflections below their respective transition temperatures,$^{12, 16, 26}$ preliminary analysis of neutron diffraction data plotted in Figs. 3(a) and 3(b) indicates no antiferromagnetic superlattice reflections at all temperatures down to 5 K. Instead, the presence of additional intensity in some of the low angle peaks confirms the presence of long range ferromagnetic order in the compound. This additional

FIG. 2. (a) Magnetization data recorded as a function of temperature for Mn$_3$InC in the 5–500 K temperature range under $H = 0.01$ T. (b) Field dependent magnetization curves for Mn$_3$InC in the 5 K $\leq T \leq 450$ K temperature range, $H = \pm 7$ T. Inset shows the behavior of the virgin curve at low fields.
Intensity is present at all temperatures below 350 K, thus ruling out the presence of a second magnetic ordering transition at 127 K as indicated by magnetization measurements. Therefore, the decrease in ZFC magnetization at 127 K could be ascribed to a short range magnetic order or canting of Mn spins.

In the case of a FM structure, the magnetic and nuclear reflections are observed at the same 2θ positions in neutron diffraction data. Consequently, the chemical and magnetic unit cells are identical. Using the basis vectors of the irreducible representations and appropriate magnetic symmetry operators generated by experimental propagation \( k = [0, 0, 0] \), the ferromagnetic structure obtained by the trial and error method and its contributions to the unmatched intensities were further identified. As shown in Fig. 3, the addition of a FM phase results in a satisfactory agreement between calculated and observed intensities of Rietveld refined diffraction patterns across the entire temperature range. The resulting magnetic structure consists of two FM sublattices identified as Mn1 and Mn2 with moment values of 1.14 + 0.13 \( \mu_B \) and 0.57 + 0.18 \( \mu_B \), respectively, as shown in the inset of Fig. 3. According to the temperature dependent variation of (100) and (110) Bragg reflections highlighted in the limited 2θ angular range in Fig. 3(b) and the refined values of lattice parameter \( a \) in Fig. 4, the unit cell volume decreases monotonically with temperature and displays no discontinuity that can be associated to a first order transition. A slight change of slope observed in the temperature variation of \( a \) at \( T \sim 127 \) K could possibly be associated with the broad magnetic transition seen in Fig. 2(a). Likewise, the thermal variation of magnetic moment calculated from neutron diffraction

FIG. 3. (a) Temperature dependent neutron diffraction patterns recorded for Mn3InC (with the Rietveld fit) in a neutron beam with \( \lambda = 1.2443 \) Å. Bragg positions indicate crystallographic and magnetic phases of Mn3InC along with excess graphite impurity. (b) Plot of neutron diffraction \( \lambda = 2.4 \) Å patterns in the limited 2θ angular range at various temperatures between 5 K and 400 K. Plots at higher temperatures have been artificially scaled up for clarity.
data for the two species of Mn atoms [see Fig. 4(b)] also shows a smooth variation in the entire temperature range suggesting that the ferromagnetic ordering in Mn3InC at 

\[ T_C = 377 \text{ K} \]

is of second order in nature.

EXAFS studies contemplating the local structure of Mn3Ga1-xSnxC compounds have highlighted the strong relation between local strains introduced by the A-site atom on the Mn6C octahedra and the magnetic properties exhibited by the respective compounds.12,13,15,16 While In atoms with an electronic configuration [Kr]4d105s25p1 contribute the same number of valence electrons as Ga ([Ar]3d104s24p1) to the Fermi level, they have an average atomic size that is similar to Sn. Therefore, the nonobservation of a first order transition to the AFM state in Mn3InC raises fundamental questions on the structural distortions of Mn6C octahedra introduced by In atoms at the A-site. Hence, in order to trace the changes in structural distortions in the local environment of the Mn6C octahedra with the introduction In, room temperature EXAFS spectra were recorded and analyzed at the Mn and In K edges of Mn3InC. Magnitudes of the \( k^2 \) weighted Fourier transformed (FT) EXAFS signals in the 3.0–14.0 Å\(^{-1} \) range used for the analysis are graphically represented in the \( R = 0 \) to 4.0 Å range in Fig. 5.

While the first peak in the Mn K edge data centered around \( R = 1.5 \) Å is due to scattering from the nearest

---

**FIG. 4.** (a) Variation of the lattice parameter as a function of temperature. (b) Magnetic moment values of Mn1 and Mn2 as a function of temperature obtained from refinement of neutron diffraction patterns of Mn3InC.

**FIG. 5.** Magnitude of the FT of \( k^2 \) weighted EXAFS spectra and the fitted curves at (a) the In K edge and (b) and (c) at the Mn K edge in Mn3InC. The corresponding back-transformed spectra in \( k \) space obtained from the \( \chi(R) \) in the limited range of 1 to 3 Å are shown for the In edge (d) and the Mn edge (e) and (f).
neighbor C atoms as in the case of Mn$_3$GaC and Mn$_3$SnC, the main peak in the $R = 1.7\text{--}2.7\text{Å}$ range arises from the combined contribution from equidistant Mn and In next nearest neighboring atoms. To begin with, a cubic structural model described by crystal structure and structural parameters ($a = 3.9924\text{Å}$) obtained from room temperature neutron diffraction patterns was used to fit the Mn K edge data in the 1 Å$\text{--}3\text{Å}$ $R$ range. While restrictions imposed by the cubic symmetry were forced upon the variation of the Mn--C, Mn--Mn, and Mn--In bond distances, the thermal mean square variation in bond distances ($\sigma^2$) was freely varied. The resulting fit in Fig. 5(b) highlights the clear deviation from cubic symmetry. Contradictorily, the same structural model used to analyze the In K edge EXAFS spectra in Fig. 5(a) (where the main peak in the range $R = 1.5\text{--}3.0\text{Å}$ solely contains contributions from the In--Mn correlation) results in a perfect fit. Thus, considering the similarities with results obtained for Mn$_3$GaC$^{12}$ and Mn$_3$SnC$^{12}$ where local distortions restricted to the Mn sublattice critically control the magnetic behavior exhibited by these materials, a structural model consisting of long and short Mn--Mn distances was designed to fit the Mn K edge data of Mn$_3$InC. The resulting good fit in Fig. 5(c) implies the presence of a structural distortion limited to the Mn sublattice. The observed distortions are similar to those observed in Mn$_3$GaC wherein the Mn atoms are displaced from their face center positions on a circular arc of radius equal to the Mn--C bond distance and the values of long and short Mn--Mn distances obtained, respectively, were 2.92 Å and 2.76 Å. Thus far, the observations of the XAFS study are quite similar to those observed in Mn$_3$GaC and Mn$_3$SnC and therefore still does not provide answer to nonobservation of the first order transition as well as antiferromagnetic ordering in Mn$_3$InC.

A comparison between the Mn K EXAFS data recorded at 300 K in Mn$_3$GaC, Mn$_3$SnC, and Mn$_3$InC in Fig. 6 perfectly highlights the variation of local structural distortions brought about by the differing size of the A-site atom. The width of the main peak in the magnitude of FT of XAFS data at $\sim 2.3\text{Å}$ decreases from Mn$_3$GaC to Mn$_3$InC. The peak itself resembles a scattering correlation between the absorber atom and a scattering atom and the width of such a peak signifies the presence of static (structural) as well as dynamic (temperature) disorder present in the compound. In the Mn K EXAFS, the peak at $\sim 2.3\text{Å}$ comprises scattering from Mn--Mn and Mn--Ga, Sn, or In correlations, while in Ga/Sn/In EXAFS, the correlation at $\sim 2.3\text{Å}$ corresponds solely to Ga/Sn/In--Mn scattering. Since the width of the first peak in Ga, Sn, and In K EXAFS recorded at 300 K is nearly the same [see Fig. 6(b)], any change in the width of the peak in Mn K EXAFS is due to

![Image](image_url)

**FIG. 6.** (a) Variation of magnitude of $k^2$ weighted FT of EXAFS spectra at the Mn K edge recorded at 300 K for Mn$_3$GaC, Mn$_3$SnC, and Mn$_3$InC. Inset shows a schematic of local structural distortions. (b) Variation of magnitude of $k^2$ weighted FT of EXAFS spectra at the Ga, Sn, and In K edges at 300 K. (c) Variation of Mn--Mn bond distances in the three compounds.
the structural disorder in the Mn–Mn correlations. It can be seen that the width of the peak in Mn K EXAFS decreases from that in Mn3GaC to that in Mn3InC, implying thereby a decrease in the local structural disorder. When the A-site is occupied by a smaller atom like Ga, the Mn6C octahedra distort freely resulting in a large separation between Mn–Mn$_{\text{long}}$ (~3.1 Å) and Mn–Mn$_{\text{short}}$ (~2.7 Å) bond distances. With the progressive increase in the size of the A-site atom from Ga ($r = 1.36$ Å) to Sn ($r = 1.45$ Å) to In ($r = 1.56$ Å), the distortions are constrained such that the difference between Mn–Mn$_{\text{short}}$ and Mn–Mn$_{\text{long}}$ decreases as illustrated in Fig. 6(c). This can be explained as follows: the size of In is about 14% larger than that of Ga, but the increase in the lattice parameter is only about 3%. This results in severe strain on the Mn6C octahedra. Therefore, despite the presence of local structural distortion, the difference in Mn–Mn$_{\text{short}}$ and Mn–Mn$_{\text{long}}$ bond distances is much less. Also, both the Mn–Mn distances being larger than 2.74 Å support only ferromagnetic interactions. However, the presence of distortions in Mn6Co octahedra leading to long and short Mn–Mn distances provides an explanation to the observation of two magnetic sublattices in the neutron diffraction analysis of Mn3InC. Furthermore, the distortions of Mn6C octahedra in Mn3InC are more closer to the ones observed in Mn3GaC than those seen in Mn3SnC. In Mn3SnC, the distortions are such that it results in longer and shorter Mn–C bond distances, which supports the presence of a small ferromagnetic moment on one of the Mn atoms and a normal magnetocaloric effect. In Mn3InC, such directional variations are not seen. Instead, the Mn atoms are displaced on a circular arc of radius equal to the Mn–C distance. A similar but much larger distortions were seen in Mn3GaC. The similarities in octahedral distortions between Ga and In containing compounds could be due to similarities in their valence electron contribution to the band states near the Fermi level.

IV. CONCLUSION

In conclusion, systematic investigations on Mn3InC reveal that it undergoes only a paramagnetic to ferromagnetic transition with a high $T_C = 377$ K. EXAFS studies suggest that, due to the larger size of In atoms, the Mn6C octahedra are strained. These strains restrict the distortions of the Mn sublattice such that the difference between Mn–Mn long and short bond distances is smaller compared to that in Mn3GaC and Mn3SnC and the value of shorter Mn–Mn distance is such that it does not favor antiferromagnetic ordering of the Mn sublattice. Thus, it appears that the magnetic ground state in such antiperovskites is decided by the distortions of the Mn sublattice, which are susceptible to the strain produced by the size of the A-site atom.
